Abstract

Purpose. This pilot study examined factors influencing classroom hearing aid use in school-age children with hearing loss.

Method. Our research team visited classrooms of 38 children with mild-to-moderate hearing loss (grades first through seventh) on two typical school days, twice per day, to document hearing aid use. In addition, parents of children reported the number of hours their child used his/her hearing aids at school.

Results. Nearly 24% of children were not observed wearing their hearing aids in the classroom on either observation day. Both grade level and degree of hearing loss appeared to impact hearing aid use. Children in fifth through seventh grade and those with milder hearing losses were less likely to wear hearing aids. Overall, parents accurately reported classroom hearing aid use; however, those with children in fifth through seventh grades were less accurate than those with children in earlier grades.

Conclusion. These preliminary results suggest that children with milder hearing loss and those in grades five through seven are at increased risk for reduced hearing aid use in the classroom. Also, parents of school-age children in these later grades are less accurate reporters of classroom hearing aid use compared to parents of children in earlier grades.

Factors Influencing Hearing Aid Use in the Classroom: A Pilot Study

Audiologists generally recommend that children with hearing loss utilize prescribed hearing technology during all waking hours. A recent report from a multi-site study reported hearing aid use time in 272 children with hearing loss, ages six months to seven years, using parent-estimates and datalogging records (Walker et al., 2013). Datalogging reports from 133 of the original 272 children revealed that average daily hearing aid use time was 8.3 hours per day, with some children showing no use of hearing aids and others showing as much as 16 hours of use per day. Such results suggest that some children are not following the recommendation of full-time hearing aid use during the first seven years of life.

Walker and colleagues (2013) also used parent-estimated daily use time to investigate factors that influence hearing aid use in these same 272 children. Children who were older, children who had moderate-to-severe hearing loss, and children whose mothers completed college had parents who reported more hours of daily hearing aid use than younger children with mild-to-moderate hearing loss and those with mothers who did not complete college. Such findings provide valuable information regarding factors that may place children at-risk for not using hearing aids consistently from birth through seven years of age. Surprisingly, research examining trends of daily hearing aid use as well as factors influencing this use in children with hearing loss who are older than seven years of age is extremely limited.

As children grow older, factors other than those addressed by Walker and colleagues (2013) may influence whether the child wears hearing aids. One potential factor

that might contribute to school-age children wearing hearing aids less than full-time could be a lack of perceived benefit due to hearing aid malfunction. Several early studies documented that hearing aid malfunction rates can occur in 27-60% of devices used by school-age children with hearing loss (Bess, 1977; Gaeth & Lounsbury, 1966; Riedner, 1978). These studies provide information regarding a potential reason for limited use of early generations of hearing aid technology. Unfortunately, they do not provide sufficient information regarding the ages of children represented in their samples, making it difficult to generalize their results to today's population of school-age children with hearing loss.

Another factor that might influence hearing aid use beyond six years of age is the changing educational environment as children continue through primary and into secondary school. For instance, full-day academic instruction often requires children to spend six-to-eight hours in classrooms with 15-30 other children and only one or two teachers. As children advance through primary school, they often receive instruction from multiple teachers in multiple classrooms. Because this educational structure yields an environment in which the teacher may have increased difficulty monitoring the use of hearing assistive technology for one of their many students, the responsibility to maintain consistent hearing aid use is generally transferred to the child. This may occur before the child is responsible enough to take on the role of hearing aid management. During this time, social pressure to "fit in" with normal hearing peers may also negatively influence how the child shoulders this new responsibility. For instance, Keilmann, Limberger, and Mann (2007) found children with hearing loss between the ages of six and eleven years to show less self-confidence than their peers with normal hearing as they reach higher grades. This reduction in self-confidence is likely a result of increased social pressure as children

advance through primary school (Elkayam & English, 2003). Low levels of self-confidence have been shown to result in reduced use of prescribed eyeglasses in school-age children (Dias, Hyman, Manny, Fern, & COMET GROUP, 2005; Holguin et al., 2006). It is reasonable to posit that children with hearing loss in this age range might show a similar decline in consistency of hearing aid use reflective of this reduction in self-confidence.

Understanding hearing aid use patterns in school-age children is a first step in beginning to examine factors that might place children at risk for inconsistent hearing aid use in the classroom. The primary purpose of this pilot study was to document the use of hearing aids during regular classroom instruction in a small sample of children with mild-to-moderate hearing loss between the ages of six and twelve years. In addition, we explored the impact of factors known to affect hearing aid use in a younger population of children (degree of hearing loss and grade-level of the child) on hearing aid use in this sample of school-age children. Finally, we examined the agreement of parent-report and direct observations of hearing aid use in the classroom. Results of this study will help inform future research examining other factors influencing hearing aid use in school-age children.

Method

Participants

Children with mild-to-moderate hearing loss and their parents were recruited from Vanderbilt's pediatric audiology clinics and school systems throughout the middle Tennessee area to participate in a larger, ongoing study examining listening effort and fatigue in school-age children with hearing loss. Mild hearing loss was defined as a pure tone average (PTA; thresholds at 0.5, 1.0 and 2.0 kHz) between 20 and 40 dB HL or

thresholds greater than 25 dB HL at two or more frequencies above 2.0 kHz. Moderate hearing loss was defined as a PTA of 45-70 dB HL in the better ear. Children exhibiting a conductive component were included in the data set as long as the sensory/neural hearing loss fit the above criterion and the hearing loss was stable (not fluctuating). Hearing thresholds were confirmed within the mild-to-moderate hearing loss range upon study entry. Children qualified for the larger study if they had no diagnosis of autism spectrum disorder or cognitive impairment as reported by the parents. All children spent at least two hours per day in a general education classroom. Participants volunteered their time and were compensated for other aspects of the more extensive, ongoing study; however, no compensation was provided for parent responses or the classroom observations reported here. Informed consent and assent were obtained for all participants in accordance with Vanderbilt University Institutional Review Board policies.

Children in this data set included 20 females and 18 males who were between 6.5 and 12.92 years ($M = 10.11$ years, $SD = 1.95$ years). All children included in this data set had personal hearing aids recommended by an audiologist. Children with cochlear implants and children with unilateral hearing loss were not included. Figure 1 shows a composite audiogram for the 38 children discussed here.

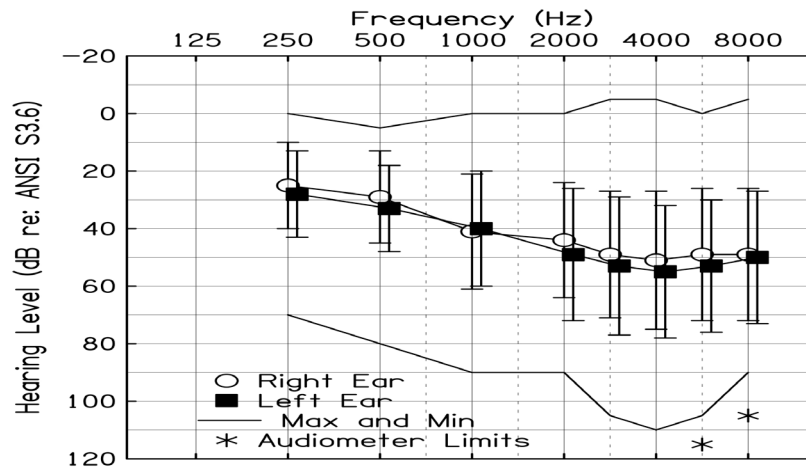

Figure 1. Average (1SD) thresholds for left (filled squares) and right (open circles) ears of children included in this data set. Solid lines represent minimum and maximum thresholds recorded from individual children. Asterisks indicate “no response” obtained at the limits of the audiometer at those frequencies for at least one participant.

Procedures

Hearing aid use was documented in two ways: parent report and classroom observation. Upon study entry, parents were asked to estimate the number of hours per day their child uses hearing aids at school. Although parents were aware that research assistants would be visiting their child’s classroom for another aspect of the study, they were not informed that their child’s hearing aid use/non-use would be documented. Classroom observations of hearing aid use were obtained as part of a larger, ongoing, project examining listening effort and fatigue in school-age children with hearing loss (see Bess, Gustafson, & Hornsby, 2014 for an overview of this larger project). Research assistants visited each participant’s classroom on two typical school days (e.g., no fire

alarm, no standardized testing) at approximately 10:00 am and 2:00 pm, for a total of four, 10-minute observations. During these observations, the research assistant documented if the child was wearing his/her hearing aids. Observation days occurred within the same week for 28 of the 38 children or within two weeks for 37 of the 38 children. One child's second observation occurred eight weeks after the first observation due to complications with scheduling (i.e., school closings due to inclement weather, illness, and a family emergency). Children were classified into one of three groups based on these four observations. Children who were not observed wearing hearing aids during any of the four observation periods were categorized into the *Non-user* group. Those children observed one, two, or three times wearing hearing aids were considered *Variable users*. If children were observed wearing hearing aids during all four observation periods, they were considered *Consistent users*.

Results

Figure 2 shows the proportion of children in each of the three hearing aid use groups. The majority of children were observed wearing hearing aids during all four classroom observation periods; however, nine children (23.7%) were not observed wearing hearing aids during any of the classroom observations. One-way analysis of variance (ANOVA) showed no significant effect of gender on hearing aid use in the classroom ($F(2, 35) = 0.021, p = .979, \eta_p^2 = .001$).

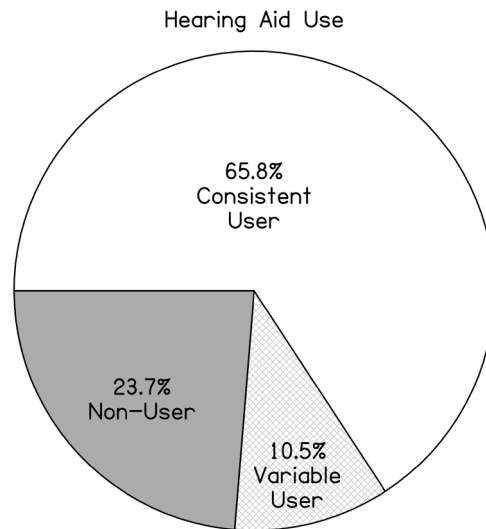

Figure 2. Proportion of children in each hearing aid use group based on classroom observations.

Degree of Hearing Loss

To examine the effect of degree of hearing loss on observed classroom hearing aid use, we conducted an ANOVA on the four-frequency, better-ear, pure-tone-average (500, 1000, 2000, and 4000 Hz; 4-PTA) among the three hearing aid use groups (Non-user, Variable user, and Consistent user). The ANOVA revealed significant differences in better-ear 4-PTAs as a function of hearing aid group ($F(2, 35) = 10.897, p < .001, \eta_p^2 = .384$). Tukey's Honestly Significant Difference post hoc test revealed hearing thresholds of the Non-user group to be significantly better than thresholds of the Consistent user group ($p < .001$). See Figure 3.

Figure 3. Better-ear four-frequency PTA (dB HL) in each hearing aid use group based on classroom observations. Box plots represent median (solid middle line) and interquartile range (25th and 75th percentile). Error bars represent the 5th and 95th percentile for each group. Filled circles represent mean data for each group.

Grade Level

Grade levels of participants ranged from first through seventh grade; six children repeated at least one grade based on parent-report. Based on anecdotal reports from children and parents, we felt that social pressure was a likely contributor to whether school-age children decided to wear their hearing aids during a typical school day. Therefore, we examined grade level, rather than chronological age, to determine if classroom hearing aid use differed across the wide developmental range included in this data set.

To examine the effects of grade level on hearing aid use we first confirmed there was no relationship between grade level and better-ear 4-PTA ($r = -.043, p = .796$). Next, because degree of hearing loss varied between hearing aid use groups, we used the better-ear 4-PTA as a covariate in an ANOVA examining grade level as a function of hearing aid group. A significant effect of hearing aid use group was present ($F(2, 34) = 6.753, p < .05, \eta_p^2 = .265$). Post-hoc pairwise comparisons revealed the Consistent use group to have a lower mean grade level (3.323) than the Variable (5.999; $p < .05$) and Non use (5.882; $p < .05$) groups. The Variable and Non user groups showed no difference in mean grade level ($p = .910$).

Figure 4 shows the number of children categorized into each hearing aid use group for all seven grade levels. Gross patterns of directly observed hearing aid use presented in this figure show mostly consistent observations of hearing aid use for children in grades one through four. A mixed pattern of hearing aid use was observed directly for those in grades five through seven. Based on this observation, we divided children into two grade-groups (one through four and five through seven) for subsequent analyses. Of the 19 children in grades one through four, 17 (89.5%) were observed wearing hearing aids during all four classroom visits (Consistent users). Conversely, only eight children (42%) in grades five through seven were observed to be Consistent users. A Mann-Whitney rank-sum test performed with grade group (one through four vs. five through seven) as the between-groups factor confirmed that this difference was significant ($U = 99.00, p < .05, \text{two-tailed}$).

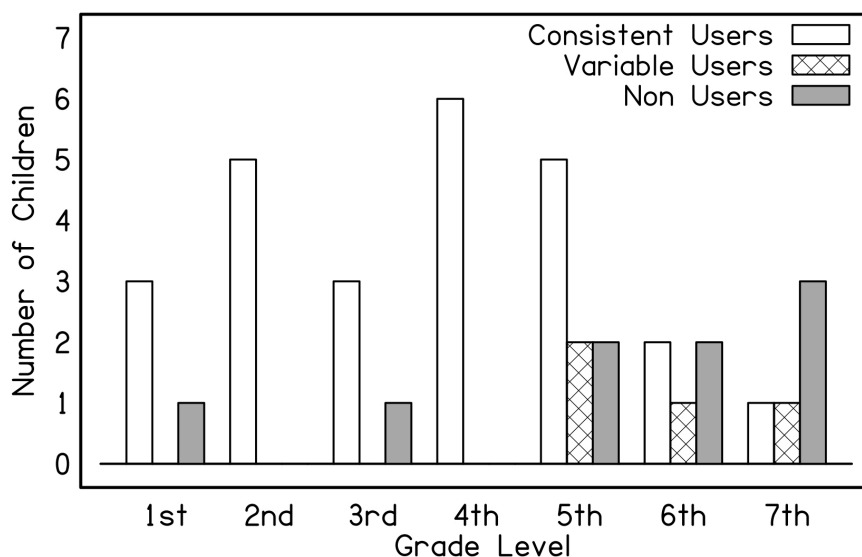

Figure 4. Number of children in each hearing aid use group based on classroom observations for each grade level.

Agreement of Parent Report & Observation

Table 1 shows the number of children in each hearing aid use group based on parent-report and classroom observation. Overall, parental report of their child's hearing aid use/non-use in the classroom agreed with our observations ($r = .744, p < .001$). A Mann-Whitney rank-sum test comparing children in grades one through four and five through seven revealed significant differences in agreement of parent-report and observation of hearing aid use ($U = 123.50, p < .05$, two-tailed). For children in first through fourth grade, parents accurately reported hearing aid use/non-use 95% of the time. Parents of children in fifth through seventh grades were less accurate, with only 63% accurately reporting use/non-use. All five parents reporting their child to be a Non-user were correct – their child was not observed wearing hearing aids during classroom visits.

Three of the nine children (33%) in the Non-user group had parents who reported them as using hearing aids during the entire school day.

Table 1. Total number of children within each hearing aid use group based on parent-report and researcher-observation.

Hearing Aid Use	Consistent User	Variable User	Non-User
Reported	32	1	5
Observed	25	4	9

Discussion

The primary purpose of this pilot study was to document hearing aid use for school-age children with mild-to-moderate hearing loss during classroom instruction. Our observations indicate that the majority of children were wearing hearing aids during each of our observations, however, almost one quarter of the children in this sample were not observed wearing hearing aids during regular classroom instruction. A secondary purpose of this pilot study was to examine if factors known to influence hearing aid use in young children might also influence hearing aid use by school-age children in the classroom. Preliminary findings showed that degree of hearing loss and grade-level are likely factors that influence classroom hearing aid use/non-use for children with mild-to-moderate hearing loss. Specifically, children in grades five through seven and those with less severe degrees of hearing loss might be at risk for reduced hearing aid use in the classroom. Our results are consistent with previous studies in younger children that show more consistent hearing aid use in children with more severe hearing loss (Muñoz, Preston, & Hicken, 2014; Walker et al., 2013). Our results of reduced hearing aid use in higher grade levels expand

upon findings from these earlier studies which reported an increase in hearing aid use time as children age from six months to seven years (Moeller, Hoover, Peterson, & Stelmachowicz, 2009; Walker et al., 2013). Because the children in our study are somewhat older and only overlap with the age-range of children reported in previous studies by two years, these divergent patterns in hearing aid use are not surprising. It is likely that hearing aid use time increases as children age from early childhood into primary school, but that use time might decrease as children transition from elementary to middle school classrooms. Combined with previous results, our findings suggest that increased monitoring of daily hearing aid use is especially important for children with milder hearing loss and those who are in grades five and above.

Another purpose of this study was to determine if parent reports of their child's classroom hearing aid use agreed with our observations. Results showed that parents are generally accurate in reporting the hearing aid use/non-use of their children; however, parents of children in grades five through seven are more likely to overestimate their child's classroom hearing aid use than those with children in earlier grades. This information is useful to audiologists working with children in fifth through seventh grade. For instance, relying on the parent report to determine if s/he is using the hearing aids at school may not yield an accurate portrayal of the child's typical classroom listening strategies. For children in these higher grade levels, it may be especially beneficial for audiologists to consider utilizing datalogging technology as a tool to obtain an accurate report of hearing aid use and for counseling purposes between the children, parents, and teachers. Of course, datalogging technology provides limited information regarding the details of hearing aid use. Datalogging has also been found to have a varied effect on

increasing a child's hearing aid use time when used as a counseling tool for families of younger children (Muñoz et al., 2014). Future studies are needed to determine if datalogging can be used successfully to increase hearing aid use in this population.

To our knowledge, this is the first study to examine systematically factors influencing hearing aid use by school-age children in the classroom. While these results provide valuable information for clinicians, teachers, and families of children with hearing loss regarding two risk factors for reduced hearing aid use at school, there are several limitations that should be considered when interpreting these results and should be addressed in future studies. For instance, observations were brief (10-minutes) and anticipated by all parties – teachers and children knew that researchers were visiting classrooms on the day of observations. This may have influenced the consistency with which some children utilized hearing aids and the awareness of teachers regarding hearing aid use. Future studies would benefit from longer and randomly assigned observation periods to provide a more naturalistic view of typical classroom hearing aid use. Additionally, the factors influencing hearing aid use examined in this pilot study were selected based on their significant effect on hearing aid use in young children reported in previous studies. In addition to degree of hearing loss and age, Walker and colleagues (2013) also found that maternal education influenced the hearing aid use time reported by the parent. The small sample size of this pilot study did not yield sufficient statistical power to examine the influence of maternal education on observed hearing aid use in school-age children. Our small sample of children also came from families who might be considered highly motivated, as all received audiologic services at a large, university medical center and were enrolled in an extensive research study requiring multiple research visits. Future

studies should consider a larger catchment of children from diverse areas and backgrounds to yield more generalizable results.

Importantly, this study does not address reasons underlying use and non-use of hearing aids in the classroom nor does it explore factors contributing to hearing aid use and non-use outside of those previously explored in a younger population. Future studies should conduct listening checks to ensure devices are functioning adequately, and ask children to discuss the reason(s) they are or are not using hearing aids. Care was taken in this pilot study not to schedule observation dates when hearing aids were out for repair (this was confirmed prior to each scheduled observation via phone call with the parent); however, it is possible that the hearing aid(s) required repair but the child or parent was unaware of the malfunctioning device(s). It is also possible that children in the Variable or Non-user groups may have stopped using their hearing aids during an observation day due to an unforeseen device malfunction. This was the case for at least one child in the Variable user group who was not wearing a hearing aid on an observation day due to a dead battery and no available replacement.

It is also unclear if children in the Variable and Non-user groups would have been considered Consistent users at an earlier age. Children in these two groups might have exhibited consistent hearing aid use early in life, but reduced the amount of hearing aid use as they advanced in grade level. Longitudinal data are needed to document hearing aid use patterns as children advance from early childhood through primary school and into adolescence. These data might allow us to identify more specific factors that influence whether or not children consistently use their hearing aids during all levels of their education. There is a paucity of data addressing potential negative consequences of

reduced hearing aid use during later stages of childhood. This type of research has the potential for motivating families, teachers, and physicians to encourage children to wear their hearing aids on a regular basis in school.

It is important that future studies examine factors in addition to the functionality of the devices that might influence hearing aid use in the classroom. For instance, assessments of psychosocial barriers to device use (e.g., peer pressure, self-esteem) might contribute to our knowledge of why school-age children decide not to wear their hearing aids. Educational factors may also influence device use in school-age children. It is not presently known whether factors such as consistent access to a Teacher of the Deaf, time spent in a general education classroom, or a classification of deaf/hard of hearing on an IEP would have an effect on the likelihood of full-time use of hearing aids. Additionally, school-age children with hearing loss are often fit with other hearing assistive technology (e.g., FM systems) in addition to personal hearing aids to help ameliorate the negative effects of poor classroom signal-to-noise ratios. It may be the case that children who have access to these additional technologies are more likely to wear their hearing aids consistently, as the combination of hearing aid and FM technology is known to provide significant benefit over the use of hearing aids alone (Hawkins, 1984).

Finally, it is interesting to note that children with mild hearing loss continue to show academic difficulties compared to their peers with normal hearing and are more often reported at increased educational risk by teachers compared to their peers with more moderate-to-severe hearing loss (Most 2004, 2006). The limited use of hearing aids during classroom instruction observed in children with mild hearing loss may play a role in their educational challenges. For example, the limited hearing aid use observed for children with

mild degrees of hearing loss would have had a direct impact of their ability to utilize a personal FM system routed through the hearing aid. Future research should explore the potentially cascading impact of reduced hearing aid use observed in this population.

The overall goal of this research report was to characterize classroom hearing aid use patterns in children with mild-to-moderate hearing loss and to explore whether risk factors known to influence hearing aid use in younger children also influence hearing aid use in school-age children. Results of our pilot study suggest that hearing aid use in the classroom is influenced by degree of hearing loss and grade level, with children in later grades and those having milder hearing loss being at risk for inconsistent hearing aid use. Audiologists and other service providers in the schools should be particularly cognizant of these hearing aid use trends when serving children beyond grade four, as our findings also suggest that parents may overestimate classroom hearing aid use in this group. Care should be taken to provide counseling to families and support for teachers of children entering these grade levels, particularly those with milder degrees of hearing loss.

Acknowledgements

The authors would like to thank Stephen Camarata, Warren Lambert, Emily Fustos, and Amanda Headley for their comments and thoughtful discussion throughout the early stages of data analysis. We are grateful to the research assistants who traveled to schools throughout Middle Tennessee to collect data and to the school districts, principals, and teachers who cooperated with our requests. Of course, this research would not have been possible without the families who agreed to participate.
